Is Education Biased? – An Ally to the Rich and a Burden to the Poor?

Vaibhav Agarwal

vaibhav.agarwal20ug@apu.edu.in

Abstract

This paper examines the impact of education across salaried, self employed and casual wage workers in urban and rural settings. I am particularly interested in determining the difference of higher education on salaried,self-employed and casual wage workers. The idea of this project is to investigate the phenomenon of difference in wages arising from a difference in education levels. The consensus in the existing literature is that education plays an important role in accruing the benefits of demographic dividend [1](Lutz et al.,2019).The literature is on the impact of higher education on earnings is small. Sikdar argues that the relationship between higher education and earnings is visible only in case of employed persons engaged in regular salaried job. People associated with other casual job, household enterprises; do not have significant relationship between wage and education [2] Sikdar(2019). The findings from this paper are that there is a difference in earnings with higher levels of education favouring the regular salaried. In case of the casual wage workers, there exists a statistically significant decline in mean earnings for higher education, differing from what Sikdar had argued. In the case of salaried employment, the returns to completing graduate education and above are higher for urban men compared to rural men.

Chapter 1

Introduction

Estimates on the rates of return to education would be a useful indicator of the reward for education in the labour market and also guide public and private investment in education.(Rani, 2014) The literature on re-turns to education is one of the most extensive in labour economics. The finding from this paper suggest that the rate of return to primary education is lower than that to post-primary levels of education. This defines the pre-existing notion of education having higher rate of returns from primary to graduate levels of education.

1.1 Relation Between Education and Earnings

Education and earnings are positively related. An increase in education will result in an increase in earnings. The change in education causes an increase in income as the education levels increase. All education levels are significant at the 1% level, ie. Thier p-values are less than 0.01. Since this is a linear-linear model, the coefficient indicate it's impact on the dependent variable in weekly wages.

The regression is facilitated with the help of dummy variables with the base as illiterates owing to the categorical nature of education. Marriage status, religion, age, caste and activity status are added as controls in the regression to contain the omitted variable bias. There were a total of 120 values with 0 wage earnings, they have been removed alongside all values with NA attributes to it. The data also filters for the working age population by removing all values where the age was less than 15 years.

Figure 1.1 is a regression with the dependant variable weekly wages on the independent variable education. Dummies for education are created with a base of the illiterate individuals. There are eleven levels of education which correspond to literates below primary(Level 0,1 and 2), Primary Education(Level 3), Secondary Education(Level 4 and 5), Higher Secondary Education(Level 6 and 7),High School Diploma or relevant degree (Level 8) Graduate Degree (Level 9) and Post Graduate and above(Level 10). Martial status, religion, age, social groups, rural/urban and employment type have been used for controls. (Henceforth, apply to all regressions)

Figure 1.1: Regressing Weekly Wages on Education

This regression table takes the illiterate population as the base. Compared to those with no formal education, workers who are literate below primary earn a higher weekly wage. Correspondingly, primary education raises average earnings by 166 rupees, middle school education by 355 rupees, secondary school by 544 rupees, higher secondary school 1350 rupees, graduate and diploma by nearly 3500 rupees, and postgraduate and above by 5000 rupees. There is a massive increasing returns to weekly wage. As education rises, weekly wages rises at an increasing rate. The paper will

1.2 Motivation and Objectives

Education as an endowment for higher wages has always intrigued me. Pursuing a bachelor's degree is accompanied by a question which leaves me at crossroads – Should I take up a master's degree after the bachelor's degree or take up a job, followed by a master's degree. Pursuing a masters is inevitable. No one questions it; it is rather when to pursue it. This makes me question, are the returns to a masters degree really that high? This paper aims at determining the returns to higher education in various opportunities of work available at the job market, namely, regular salaried, self employed and casual wage work. Furthermore, I also investigate the relationship between weekly wages in an urban setting and a rural setting.

1.3 Data and Methodology

To understand whether there is a significant relation between higher education levels and activity status(Regular salaried, self employed and casual wage workers), I have used the Periodic Labour Force Survey data for the year 2018-19. This data is nationally representative and surveys a total of 4,20,757 households. Alongside CMIE and NSSO, the PLFS dataset is regarded one among the top Indian data sets on employment data with a vibrant survey which that relevant questions on work, wages, health and many more.

weekly wages as the dependant variable, dummies for education(g.edu) as the independent variable have been used. Salaried, self employed and casual wage workers have been identified using the current weekly wage activity status(cwas) variables. Control for omitted variable bias in the regression model are addressed using the variables of marriage(marital), religion(religion), age(age), caste(social_group) and rural/urban(sector). These variables have been manipulated using the pandas package in python to assist in making dummies.

In order to carry out the empirical exercise and visual representation of the data, this paper uses the following python modeuls

1. To clean and manipulate data, Pandas and Numpy will be used
2. To conduct regression analysis statsmodels wil be used
3. To visualize the data matplotlib and geopandas will be used

To understand whether there is a significant relation between higher education levels and activity status (Regular salaried, self employed and casual wage workers) I have used a simple ordinary least squares regression. I have used this regression as the dependant variable is wages and not a binary variable. A two way fixed effects model is not used as the data set is not panel and aggregate levels of wages are used as opposed to state wise. An OLS regression is hence the best alternative as it would yield in the desired estimate of effects I intended. This regression model used is specified below:

$$Wage_i = \beta_0 + \beta_1 Education_i + \beta_2 Married_i + \beta_3 Religion_i + \beta_4 Age_i + \beta_5 Caste_i + \beta_6 Area_i + \beta_7 Activity_Status_i + \epsilon_i$$

This paper also estimates if in the case of salaried employment, the returns to completing high school education and above are higher for urban men compared to rural men. This is repeated for self employed and casual wage workers as well. The regression model used is specified below:

$$Wage_i = \beta_0 + \beta_1 Graduate_i + \beta_2 Region_i + \beta_3 Graduate * Region_i + \epsilon_i$$

Aside from these regressions, this paper also uses plenty of visualizations to aid the reader in the interpretation of the results.

1.4 Descriptive Statistics

The heat-map of India above depicts the ratio of illiterates to the total sample which is representative of India's population. From the perspective of this study, it is enough to keep the following takeaways from the map. Firstly, Kerala and the Northeastern states have the highest level of literacy rates. Secondly; Bihar, Rajasthan, Telengana and Andhra Pradesh can be seen to have low literacy levels.

Ratio of Graduates to Representative Sample of Population of States

Let us look at another heat-map of India which shows the ratio of graduates in India to the total sample which is representative of India's population. The southern have a higher number of graduates, particularly Tamil Nadu and Andhra Pradesh. It is interesting to see that Telenagna is a state with low levels of literacy and a high number of graduates. For the purpose of this study, keeping in mind the states with low literacy and high number of graduates will help.

At lower levels of education, there is high wage disparity among males and females. An additional level of education would endow the males with higher returns as compared to females. Post high school education, the earnings of females significantly improve. Males experience a steady rise in weekly wages post rise in every level of education. The aspect of gender is outside the purview of the this study.

Chapter 2

Findings

At no levels of education, regular salaried, self employed and casual wage workers earn roughly the same amount of weekly wages. For regular salaried employment, there is an increase in weekly wages at every subsequent level of educational attainment. The divergence is massive post secondary schooling where weekly wages encounter a big jump. For self employed, an increase in weekly earnings with rise in educational endowments highlights the same trend as observed in salaried employment. Casual wage workers have a negative statistically significant relationship with higher educational levels, contrary to salaried and self employed workers, wherein an additional level of education post diploma yields in a fall in earnings. The job requirement levels for casual wage workers may be a reason, this study however, does not investigate the same.

Males across all educational levels and all occupation types earn more than females. Female earnings, across all activity status, show no sign of increment until she finishes her diploma or higher secondary. The negative relationship of higher education and weekly wages can be narrowed down to just men engaging in casual work as women engaging in casual work tend to benefit from higher education levels. This paper also observes how, females, in general, particularly in self employed and casual wage work, benefit more than men in terms of weekly earnings from higher education.

In the case of salaried employment, the returns to completing high school education and above are higher for urban individuals as compared to rural individuals. Literacy plays a huge role in determining weekly wages, particularly in casual wage work. States with higher literacy rates are associated with higher mean wages in casual work and vice versa.

2.1 Education and Occupations – Regression Results

Refer to figure 4.1,4.2,4.3 in Chapter 4 – Regression Tables

From *Figure 4.1* we can see that returns to regular salaried employment increase as we increase the levels of education. The returns to education after completing primary level of schooling, i.e in secondary school and beyond is statistically significant at the one percent level of significance with a p-value less than 0.01. With an increase in education levels, a regular salaried individual will see a rise in his weekly wages. Higher education, particularly education after secondary schooling which includes diploma, a bachelor's degree or a masters and Phd show a significant increase in average earnings, around 3000 to 6400 rupees weekly.

Figure 4.2 showcases the same trends we observed for regular salaried workers in *Figure 4.1*. We can see that returns to regular self employed individuals increase as we increase the levels of

education. The returns to education after completing primary level of schooling, i.e in secondary school and beyond is statistically significant at the one percent level of significance with a p-value less than 0.01. The increase in weekly wages with higher levels of education is a mirror image of the salaried wages. The magnitude of the increase is much more in regular salaried employment as compared to self employed, ranging from 1100 to 2100 rupees.

Casual wage workers tend to have the highest weekly wages post primary schooling and before pursuing higher education, i.e diploma or a bachelor's degree(Around 325 to 350 rupees per month). *Figure 4.3* gives us an interesting story. A statistically significant reduction is seen from 620 rupees to 350 rupees post a bachelor's degree for casual wage workers. This is in opposition to the trends seen in salaried and self employed workers. Higher education has a negative impact on the wages of casual wage workers. This finding hence, denies the presence of higher wages with higher educational endowments conditioning it to the type of employment.

2.2 Education and Occupations – The Visual Picture

The figures attached below conveys clearly a picture of trends across education levels. These trends are not the same across salaried, self employed and casual wage workers. To begin with, the difference in weekly earnings can be seen among the groups. At no levels of education, regular salaried, self employed and casual wage workers earn roughly the same amount of weekly wages. At higher levels of education, deep steps amongst the three occupation types can be seen, indicative for vast differences among the latter. The positive relation between higher education levels and wages hold true for salaried and self employed workers; does not hold true for casual wage workers.

2.3 Education, Employment and Gender

At a first glance, it is hard not to observe, how males across all educational levels and all occupation types earn more than females, with only one exception of highly educated casual wage females who earn more than their counterparts. Across all activity status, women's earnings show no sign of increment until they finish their diploma or higher secondary. The negative relationship of higher education can now be deduced to only casual wage men. Females tend to benefit from higher levels of education. Females tend to benefit more than men in case of self employed and casual wage work with higher education levels. The visualizations are representative of the trends highlighted in the above section using regressions.

2.4 Higher Education in Urban vs. Rural Areas

Refer to figure 4.4,4.5,4.6 in Chapter 4 – Regression Tables

A regression with dummy variable – Area was conducted. The parameters used for this regression are :

1. Region – Rural is takes the value of 0 and urban takes the value of 1(In the PLFS dataset, urban takes value of 2 which has been changed to 1)
2. High level of education – All education levels above high school take the value of 1, all below high school education take the value of 0.
3. Region * High Education – This is an interaction variable which takes the value 1 only if the person belongs to a rural region and has completed high school education and above. The coefficient of this variable will highlight the impact of returns in salaried employment, after completing education of at least high school or above in rural areas. If the coefficient is positive, we have verified the statement and conclude that in the case of salaried employment, the returns to completing high school education and above are higher for urban individuals as compared to rural individuals.

In the case of salaried employment, the returns to completing high school education and above are higher for urban individuals as compared to rural individuals. The trends in urban rural education and wage differentials is worth mentioning only in the case of salaried employment.

2.5 Determining the Impact of Education in Casual work

This section does not talk about one's educational levels, rather those who are not educated and literate. As seen in the previous sections, Kerala and the northeastern states had the highest literacy rates. The graph below shows the average wages of casual wage workers. Kerala, the northern eastern states alongside the other states follow a pattern. States with higher levels of literacy, tend to have higher average wages and states with lower literacy levels tend to have lower average wages, particularly in the case of casual wage workers. This paper does not prove it empirically.

Average Wages of Manual Workers Across States in India

Chapter 3

Conclusion and Discussion

This paper presents the effect of education, particular higher education on weekly wages with respect to the regular salaried, self employed and casual wage workers in the rural and urban setting. Males tend to earn more than females, Higher levels of education translate to higher weekly wages, the returns to higher education are higher in an urban setting in the case of salaried employment. The relation between higher education and returns to education in the form of weekly wages does not hold true for casual wage workers. While salaried and the self employed workers experience a continuous rise in income with every additional level of education, in the case of casual wage workers, this is not true, particular for men, education does not seem to play a role in their job markets. The type of job offered to the casual wage workers is an probable answer to why the relationship between education and earnings does not seem to hold true. Most often, the casual wage workers are underpaid, exploited and given no benefits with their jobs. To conclude, the results from this paper are worth a discussion in policy forums. Aside from a minimum wage, a minimum standard for all jobs must be put across India, exploitation of any kind must be severely punished. We must devise new strategies to promote education for the casual wage workers and incentive them to get educated.

Figure 4.6: Higher Education and Occupation: Casual Wage Workers

Chapter 5

Appendix

The graphs depicting the state wise distribution of mean wages of salaried and self employed workers do not display any noticeable trends. The distribution of salaried and self employed workers are uniform through out India. There exist higher mean wages in the north-eastern states but there is no conclusive reasoning for the same. One interesting observation lies in the color of both the graphs; regular salaried having a lighter shade uniformly indicating higher weekly wage. These graphs are only attached for the curious reader.

Figure 5.1: Mean Earnings: Regular Salaried

Figure 5.2: Mean Earnings: Self Employed
